Abstract
Air quality monitoring has been lacking in the rural and western North West Province. Here ambient sulphur dioxide (SO\textsubscript{2}), nitrogen dioxide (NO\textsubscript{2}) and ozone (O\textsubscript{3}) concentrations, monitored with passive samplers at 10 sites, are presented. Widespread SO\textsubscript{2} and NO\textsubscript{2} problems weren’t observed. However, regular O\textsubscript{3} standard limit exceedances are likely across the province. Increased SO\textsubscript{2} and NO\textsubscript{2} concentrations in the colder and drier months were evident. Inversion layer trapping of low-level emissions during the colder months and open biomass burning in the drier months increased ground level pollutant concentrations. Wet deposition of SO\textsubscript{2} and NO\textsubscript{2} and enhanced SO\textsubscript{2} conversion to particulate sulphate, result in lower wet season concentrations. O\textsubscript{3} concentrations were lower from May to July and higher from August to March. Three phenomena contributed to this. Firstly, shorter daylight hours (less photochemistry) and secondly, lower biogenic volatile organic compound (O\textsubscript{3} precursors) concentrations during the colder months. Thirdly, the late winter/early spring open biomass burning peak lead to elevated carbon monoxide (CO) concentration (also an O\textsubscript{3} precursor). Spatial patterns indicated higher SO\textsubscript{2} concentrations in the west, due mainly to industrial emissions. The NO\textsubscript{2} spatial map indicated two areas of higher concentration, i.e. Bapong in the east due mainly to industrial emissions, and Taung with its higher population density. The O\textsubscript{3} spatial map was almost the inverse of NO\textsubscript{2}, the lower O\textsubscript{3} and higher NO\textsubscript{2} around Taung indicated that O\textsubscript{3} is likely titrated there. Additionally, the results indicate that non-point source emissions of NO\textsubscript{2} are high enough to results in exceedances of the O\textsubscript{3} standard limit. Overlay back trajectory maps showed that sites in the east are more frequently impacted by pollution transported from the Mpumalanga Highveld, Vaal Triangle and the Johannesburg-Pretoria megacity if compared to the west. Conversely, cleaner air masses impact the west more than sites in the east.

Introduction
Anthropogenic activities are increasing the ambient tropospheric concentrations of inorganic gaseous pollutants, which include nitrogen dioxide (NO\textsubscript{2}), sulphur dioxide (SO\textsubscript{2}) and ozone (O\textsubscript{3}). These species are globally considered as important pollutants and are criteria pollutants according to the South African National Environment Management: Air Quality Act of 2004 (Government Gazette 2005). Human health issues associated with NO\textsubscript{2} and nitrogen oxide (NO) (combined referred to as NO\textsubscript{x}) as well as SO\textsubscript{2} include irritation of the respiratory system, which can cause breathing difficulties. People who suffer from asthma are particularly sensitive to chronic inhalation of elevated NO\textsubscript{x} and SO\textsubscript{2} concentrations, which may result in long-term effects such as pulmonary asthma and chronic bronchitis (Pandey et al. 2005). Exceedances of the South African NO\textsubscript{2} and SO\textsubscript{2} ambient air quality standard limits have been reported for numerous locations/areas (e.g. DEA 2010).

Oxidation of SO\textsubscript{2} and NO\textsubscript{2} lead to the formation of sulphate (SO\textsubscript{4}\textsuperscript{2-}) and nitrate (NO\textsubscript{3}\textsuperscript{-}), respectively. In South Africa it has been indicated that these species contribute significantly to the acidity of atmospheric particulate matter (Venter et al. 2018),
acid rain (Conradie et al. 2016), eutrophication of the terrestrial and aquatic environment (Dunnink et al. 2016), and secondary aerosol formation (Vakkari et al. 2015). SO$_2$ and NO$_x$ also scatter radiation (IPCC 2013) and are important species within the context of aerosol climate forcing in South Africa (Venter et al. 2020).

Tropospheric O$_3$ is a secondary pollutant formed from the photochemical reaction of NO$_x$ (Seinfeld and Pandis 2016). O$_3$ can have deterrential impacts on crops and vegetation (Laakso et al. 2013). Additionally, O$_3$ is a short-lived greenhouse gas, which has a net warming effect (IPCC, 2013). Exceedances of the Southern African O$_3$ air quality standard limit has been reported for large areas of the South African interior (Laban et al. 2018).

Major sources of atmospheric pollutants in South Africa include fossil fuel combustions, traffic, open biomass burning (veld fires), mining and metallurgical activities, and household combustion. The Mpumalanga Highveld, Johannesburg-Pretoria (JHB-Pta) megacity and the Vaal Triangle are all regions that are relatively polluted and where ambient air quality standard limits are regularly exceeded (Government Gazette 2012, 2020). In addition, numerous large point and area sources are located in the western Bushveld Complexes (wBC) (Rustenburg, Brits and Sun City areas) within the North West Province. This area was included in the Waterberg Priority Area (Government Gazette, 2010), due to current and possible future exceedances of ambient air quality standard limits there. Typical sources of pollutants in the wBC include pyro-metallurgical smelters, mining activities, household combustion, open biomass burning and vehicular emissions (Piketh et al. 2005).

Due to the above-mentioned air quality issues associated with the Mpumalanga Highveld, JHB-Pta megacity, Vaal Triangle and wBC, numerous regulatory and research studies are/have been conducted there. However, to the knowledge of the authors, no systematic air quality studies have been conducted in the rural areas of the western North West Province. Therefore, the general aim of this study was to assess SO$_2$, NO$_x$ and O$_3$ concentrations in rural areas of the North West Province. The specific objectives were to: i) measure SO$_2$, NO$_x$ and O$_3$ with a cost effective manner at 10 sites for at least two full seasonal cycles; ii) contextualise SO$_2$, NO$_x$ and O$_3$ concentrations, in terms of air quality standard limits, as well as with measurements conducted elsewhere; iii) establish seasonal and spatial patterns of the pollutant species; iv) indicate possible sources and/or contributing factors and v) give guidance to possible future ambient measurements of SO$_2$, NO$_x$ and O$_3$ in the area.

**Experimental**

**Passive sampling and associated analytical methods**

Since the rural North West Province covers a large surface area, it was impractical (too expensive and logistically difficult) to conduct this study with active sampling. Therefore, passive diffusive samplers developed by the North-West University (NWU) (Pienaar et al. 2015) were used to measure monthly average concentrations. Although passive samplers do not give instantaneous concentration values (as with active samplers), they are ideal to map a large region and identify potential areas where higher resolution measurements should be conducted.

Passive sampler preparations were conducted as specified by Dhammapala (1996) with sodium hydroxide (NaOH) dissolved in methanol, NaOH and sodium iodide (NaI) dissolved in methanol, and sodium nitrite (NaNO$_2$), potassium carbonate (K$_2$CO$_3$) and glycerol dissolved in a water-methanol mixture used as adsorbent solutions for SO$_2$, NO$_x$ and O$_3$, respectively. After preparation, each sampler was labelled according to the preparation date, designated site and pollutant species. Thereafter, each sampler was placed in an airtight plastic vial and sealed in an airtight bag. For each pollutant species a laboratory blank sampler was prepared for every monthly sample batch that was deployed. These blanks were sealed and stored in the laboratory freezer until analysis.

The passive samplers were deployed and exposed in pairs for each pollutant species. Exposure of pairs reduced data loss should a specific sampler suffer any sort of interference. A log sheet was kept for every sampler, in order to record important variables needed for calculations and/or observations that would assist in explanations (e.g. exposure and collection times and date, and unusual events such as nearby fires). The passive samplers were exposed by placing them in a stainless-steel rail, mounted under an aluminium sampler hood. Hoods were either attached to an aluminium shaft and stand base, or a bracket that was screwed onto a suitable structure (e.g. wooden power/telephone pole, or road sign) approximately 1.5m above ground level. The sampler hood act as a shield, which protect the exposed samplers against direct sunlight and rain.

After the exposure period was complete, the passive samplers were removed, sealed in plastic vials and bags. Directly thereafter, fresh unexposed samplers were deployed for the following month. Exposed samplers were sent back to the lab for analysis. Upon receipt, the samplers were logged as received and stored in a freezer until analysis.

In preparation for chemical analysis, the pollutant specific impregnated filters of the passive samplers were leached as previous specified (Dhammapala 1996, Pienaar et al. 2015). Analyses of the leached solutions were conducted with an ion Chromatography Dionex ICS 3000 system, fitted with an Ionpac AS16 (4 mm) analytical column, an AS16 guard column (4 mm) and a conductivity detector. Background conductivity was lowered by a self-regenerating electrochemical suppressor (4 mm AERS-500), fitted with a carbonate removal device. The flow rate was maintained at 1.2 cm$^2$min$^{-1}$. The system was also equipped with an eluent (hydroxide, OH-) generator. Calibration of the IC was conducted using stock solutions with concentrations of 0.02, 0.2, 0.8, 1.5 and 2.5 µmol.dm$^{-3}$ of the relevant chemical species.
The combination of passive samplers and analytical procedure have been used in numerous published studies (e.g. Swartz et al. 2020, the most recent). In addition, the accuracy (how close to calibrated active samplers) and precision (repeatability) of the passive samplers have been demonstrated in national (Dhammapala 1996) and international (Pienaar et al. 2015) inter-comparisons. Quality assurance of the analytical procedure was further verified by participating in the bi-annual Laboratory Inter-Comparison Study (LIS) organised by the World Meteorological Organisation (WMO) (e.g. as presented in Conradie et al. 2016, Swartz et al. 2020).

Ancillary data
Air mass movements were determined by calculating 96-hour back trajectories for air masses arriving at a height of 100m above ground level, for every hour during the sampling campaigns. This was done by using the Hybrid Single-Particle Lagrangian Integrated Trajectory model (HYSPLIT, version 4.8) (Draxler and Hess 2004). The model was run with meteorological data of the Global Data Assimilation System (GDAS) archive of the National Centre for Environmental Prediction (NCEP) of the United States National Weather Service and the Air Resources Laboratory (ARL) archive, accessed 01/09/2020.

Overlay back trajectory maps (introduced in Vakkari et al. 2011) were compiled in order to get an overview of air mass movement for a specifics site during specific measurement months, or for the entire measurement period. In such maps a colour code was used to indicate the percentage of the hourly arriving trajectories passing over 0.2º x 0.2º grid cells that were superimposed on the South African map, with the colours red and blue indicating the highest and lowest percentage overpasses, respectively.

The National Aeronautics and Space Administration (NASA) Moderate Resolution Imaging Spectrometer (MODIS) collection 5 burned area product (Roy et al. 2008) was used to determine open biomass burning fire locations. Such data is expressed as gridded 500 m fire burn scar pixels (Boschetti et al. 2009, 2013).

Measurement campaigns
Monthly $\text{SO}_2$, $\text{NO}_2$, and $\text{O}_3$ measurements were conducted at 10 sites during two sampling campaigns, i.e. April 2014 to March 2015 and February 2018 to October 2019. In addition, a more intensive campaign was conducted in June, July and August (JJA) 2019. During this intensive campaign, 15 additional sites were monitored. The additional sites were located mostly in-between (via tar road access) the 10 sites that were monitored over the entire time, during both campaigns. The intensive campaign was done for two reasons. Firstly, to distinguish whether the trace gas concentrations at the 10 sites, which were located in small urban areas, differed from concentrations in-between the urban areas. Secondly, the larger number of sites made it possible to obtain a better spatial representation of pollutant concentrations across the province.

Measurement sites
The Directorate Environmental Quality Management; Rural,
However, it (the spatial distribution) is discussed in spatial distribution and is therefore not considered further here.

Taung and Tosca had the lowest median and mean SO$_2$ concentrations, of 0.38 and 0.40, and 0.39 and 0.43 ppb, respectively (Figure 2a and Table A1, Appendix). These median/mean concentrations compare well with the mean SO$_2$ concentrations reported by for Okaukuejo in Namibia (0.43 ppb), a relatively unpolluted southern African continental background site (Martins et al. 2007). Bapong had the highest median and mean SO$_2$ concentrations of 2.55 and 2.67 ppb, respectively, which were significantly higher than the other sites considered in this study. The Bapong median/mean concentrations were lower than the 3.80 ppb reported for Marikana (Venter et al. 2012) located close to several smelters in the North West Province (Venter et al. 2012), and is lower than the 8.50 ppb reported for Marikana (Venter et al. 2012).

For SO$_2$, annual average concentrations (calculated from April’14 to March’15 and February’18 to January’19) for all 10 sites varied between 0.35 to 2.63 ppb, which is substantially lower than the specified 1-year average limit of 19 ppb (Government Gazette, 2009). To contextualise the monthly results within the context of ambient air quality standards limits, a curve fit was applied to the 10 min., 1-hr., 8-hrs., 24-hrs and 1-year standard limits specified for SO$_2$ (Government Gazette, 2009), as indicated in Figure A1 (Appendix). By using the equation of the fitted curve, it was possible to estimate a potential monthly average “limit” value, which was found to be 29.53 ppb. Comparing the monthly SO$_2$ concentration values with the afore-mentioned calculated value indicated that if a monthly limit did exist for SO$_2$, it would likely not have been exceeded during the measurement period. However, the impacts of SO$_2$ is not a continuum across a wide concentration range (Katsouyanni et al. 1996), therefore, the method applied here is a simplification of reality, but it does give
some quantitative indication of monthly average SO$_2$ air quality. Venter et al. (2012) indicated that on average 4, 0.4 and 0 exceedances of the 10-min (191 ppb), 1-hr (124 ppb) and 24-hrs (48 ppb) SO$_2$ standard limit values occurred at Marikana, which is approximately 17.5 km (measured in a straight line) from the Bapong site. The average SO$_2$ concentration measured at Bapong was 2.67 ppb, while that of Marikana was reported as 3.80 ppb (Venter et al. 2012). Therefore, it might be possible that some exceedances of the 10-min and 1-hr standard limit values occurred at Bapong. However, the number of such exceedances are unlikely to be close to the 52 and 88 allowed frequency of exceedances specified for the 10-min and 1-hr standards, respectively (Government Gazette, 2009). It is also unlikely that such exceedances will occur at any of the other sites, since the SO$_2$ concentrations were significantly lower there (Figure 2a).

For NO$_2$, annual average concentrations (April’14–March’15 and February’18–January’19) for all 10 sites varied between 1.28 to 5.90 ppb, which is substantially lower than the specified 1-year average standard limit of 21 ppb (Government Gazette, 2009). As previously stated, it is impossible to directly compare monthly average values with shorter standard limit period, such as the 1-hr. standard limits specified for NO$_2$. It is also impossible to estimate a monthly standard “limit” for NO$_2$ (as illustrated for SO$_2$ in Figure A1, Appendix), as there are only two standard limit values specified in the current legislation (Government Gazette, 2009). Similar to the SO$_2$ results, Bapong again had the highest NO$_2$ concentrations. The average NO$_2$ concentration measured throughout the sampling periods at Bapong was 5.55 ppb, while that of Marikana was reported as 8.50 ppb (Venter et al. 2012). Since Venter et al. (2012) did not report any exceedance of the 1-hr standard limit at Marikana, it is unlikely that NO$_2$ concentrations at Bapong, or any of the other measurement sites, exceeded the 1-hr standard limit of 106 ppb.

O$_3$ only has an 8-hrs. moving standard limit of 61 ppb (Government Gazette, 2009), therefore, it was impossible to directly indicate exceedances of the afore-mentioned standard limit. However, as indicated in Section 2.3 an intensive campaign was undertaken, during which concentrations of the
three pollutants of interest were measured at 15 additional sites during JJA 2019. During this JJA period the O₃ concentrations were highest at Bapong, Ottsoshoo and Morokweng, i.e. 34.33, 32.50 and 31.75 ppb, which are similar to the Welgegund and Botsalano JJA calculated O₃ values of 36.62 and 32.69 ppb, respectively. The lowest O₃ concentrations during the JJA period were measured at Taung, Schweizer-Reneke and Vryburg, i.e. 24.33, 22.71 and 22.70 ppb, respectively, which were similar to the JJA value of 23.21 ppb calculated for Marikana. Relatively recently Laban et al. (2018) presented the average number of days per month on which the O₃ 8-hrs moving average standard limit were exceeded at the afore-mentioned reference sites, i.e. Welgegund (up to approximately 9.9 days per month), Botsalano (up to approximately 5.4 days per month) and Marikana (up to approximately 12.1 days per month). Considering the similarly in JJA O₃ average concentrations measured during this study with the afore mentioned published data (Laban et al. 2018), it is highly likely that significant number of O₃ exceedances also occurred at all the sites where measurements were conducted in this study.

Seasonal patterns
The monthly average concentrations (average for all January concentrations, average for all February concentrations, etc.) for SO₂ (a), NO₂ (b) and O₃ (c) are presented for each site separately, combined for both measurement campaigns, in Figure 3. In Figure 4 statistical distribution of combined monthly concentrations (all January concentrations, all February concentrations, etc.) for SO₂ (a), NO₂ (b) and O₃ (c) for all sites combined over both sampling campaigns, are presented as boxplots. The latter gives a regional (Figure 4), rather than a site specific (Figure 3) perspective on seasonal patterns.

From both Figures 3(a and b) and 4(a and b), a relatively well-defined and similar seasonal pattern is evident for SO₂ and NO₂, i.e. higher concentrations in the colder months of June to August, as well as late autumn (May) and early spring (September), while the rest of the year has lower concentration values. Similar seasonal patterns have previously been reported for other areas in South Africa (Josipovic et al. 2010). This seasonal pattern indicates possible additional contribution from sources such as household combustion for space heating that occurs more frequently in the colder months (Adesina et al. 2020), as well as open biomass burning that occurs more frequently in the drier months (Chiloane et al. 2017). Additionally, enhanced trapping of low-level emissions during the colder months by a low-level inversion layer(s) lead to increased concentrations of pollutants at ground level (Garstang et al. 1996). Gierens et al. (2019) reported the formation of such a low-level thermal inversion layer to occur approximately 81% of the time during JJA at Welgegund in the North West Province, while it only occurred approximately 33% during December, January and February (DJF). Also, the daily persistence of the low-level thermal inversion layer is longer during JJA, if compared to DJF (Gierens et al. 2019). Furthermore, increased wet deposition of both SO₂ (as SO₄²⁻) and NO₂ (as NO₃⁻) (Conradie et al. 2016), as well as enhanced conversion of SO₂ to particulate SO₄²⁻ that occur during the wet season when the relative humidity (RH) is higher (Seinfeld and Pandis 2016), result in lower gaseous concentrations during the warmer/wetter months. Unfortunately, rain volumes and RH were not measured at any of the 10 sites considered in this study, but it was measured at Welgegund. Figures A2a and b (Appendix) present the rain events and RH measured at Welgegund during the first measurement campaign (April 2014 to March 2015), respectively. As is evident, rain events are frequent during the rainy season (approximately middle October to end of March), with very few events during the rest of the year. RH is lower from approximately May to October.

In contrast to the SO₂ and NO₂ seasonal patterns, O₃ concentrations (Figures 3a and 4a) were on average lowest during the colder months of May to July and higher in the period August to December, as well as January to March. Similar seasonal O₃ patterns have previously been presented for Welgegund, Botsalano and Marikana (Laban et al. 2018), which are all situated in the North West Province. Similar to Laban et al. (2018), three phenomena can be considered to partially explain the observed O₃ season pattern. Firstly, the colder months have shorter daylight hours, hence less time for photochemical formation of O₃. Secondly, biogenic volatile organic compound (BVOC) emissions in the North West Province are lower during the colder months (Jaars et al. 2016). VOCs are important within the context of O₃ formation, since the alkylperoxy radical (ROO•) that form during the oxidation of VOCs convert NO to NO₂, from which O₃ is formed (Seinfeld and Pandis 2016). Thirdly, the peak in open biomass burning in the interior of southern Africa during late winter and early spring (typically August to mid-October) (Chiloane et al. 2017) also lead to a peak in carbon monoxide (CO) concentrations in the North West Province (Laakso et al. 2008). The oxidation of CO results in the formation of the hydroperoxy radical (HO₂•), which similar to the ROO• radical enhance conversion of NO to NO₂ (Seinfeld and Pandis 2016). As an example, the frequencies of open biomass burning within 100 and 250 km radii around the Bapong site are presented in Figure 5, for the first measurement campaign. This data clearly indicates a peak in such events during late winter and early spring, which correspond with higher ambient O₃ concentrations. All sites
Spatial distribution

Site specific SO$_2$, NO$_2$ and O$_3$ concentrations were statistically presented in Figure 2. The highest SO$_2$ concentrations were measured at Bapong (2.55 median and 2.67 ppb mean) throughout the entire sampling period, while the second highest SO$_2$ levels were measured at Ottoshoop (1.12 median and 1.13 ppb mean) (Figure 2a and Table A1, Appendix). Bapong is situated within the wBC that is part of the Bojanala Platinum district, where a large number of platinum group metal (PGM) and base metal (Xiao and Laplante 2004), ferrovanadium (Moskalyk and Alfantazi 2003), as well as ferrochromium smelters (Venter et al. 2016) occur. Situated relatively close (i.e. 13 to 45 km) to Ottoshoop are three cement factories with kilns, while Mahikeng, the capital of the North West Province, is situated 33 km to the west southwest.

NO$_2$ concentrations were the highest at Vryburg (5.52 median and 5.16 ppb mean), Bapong (5.26 median and 5.55 ppb mean), Taung (4.68 mean and 5.18 ppb) and Schweizer-Reneke (4.02 median and 4.22 ppb mean) (Figure 2b and Table A1, Appendix). As indicated in the previous paragraph, Bapong is situated in an industrial area, where higher pollutant concentrations can be expected. Both Vryburg and Taung are areas with larger population densities than most of the rural sites considered in this study, hence vehicle and/or household combustion emissions of NO$_2$ will be more significant. Similarly, vehicle emissions are thought to be the main source of the higher NO$_2$ concentrations reported for Schweizer-Reneke, since the measurement site was located at a municipal building on a relatively busy intersection. The lowest NO$_2$ levels were consistently measured at Tosca and Morokweng, which are both rural areas with very low population density and no significant industrial activities.

In contrast to NO$_2$, the highest O$_3$ levels were measured at Morokweng (33.61 median and 34.97 ppb mean), Ottoshoop (33.51 median and 34.74 ppb mean) and Tosca (30.99 median and 30.17 ppb mean), while the lowest O$_3$ concentrations were measured at Taung (24.19 median and 23.92 ppb mean), Vryburg (25.02 median and 25.47 ppb mean), and Schweizer-Reneke (27.44 median and 27.63 ppb mean) (Figure 2b and Table A1, Appendix). Bapong was the exception, since it had higher O$_3$ and NO$_2$ levels, while NO$_2$ and O$_3$ were inverse of one another at most other sites. SO$_2$ is a primary pollutant, while NO$_2$ can be a primary pollutant, but it is mostly a secondary pollutant that

Thus far, air mass histories were not considered in explaining the observed seasonal patterns (Figures 3 and 4), although it is well-known that it can play an important role (Garstang et al. 1996, Tyson and Preston-Whyte 2000). To illustrate the importance thereof, hourly arriving 96-hour back trajectories for the DJF and JJA periods during both sampling campaigns for Bapong (again used as an example site) are presented in Figure 6. From this example, it is evident that the principal flow of air masses towards Bapong (indicated by red) during DJF (Figure 6a) follows an anti-cycloonic pattern, with dominance from the sector between north northwest to northeast. There is limited airflow from the south (indicated by yellow). During the JJA period (Figure 6b) the anti-cycloonic pattern is still evident, but much more air masses pass over the area directly south of Bapong (indicated by red), where the relatively polluted Johannesburg-Pretoria (JHB-Pta) megacity lie (Lourens et al. 2011 and 2016). Also, more air masses pass over the fairly polluted Mpumalanga Highveld during the JJA period. This example indicates that in additional to local sources and local meteorological contributing factors, regional transport of pollutants could contribute to the observed concentrations. Specifically, SO$_2$ and NO$_2$ transport from the JHB-Pta megacity, the Mpumalanga Highveld, the Vaal Triangle and the wBC could have impacts on a regional scale.

Figure 6: 96-hour overlay back trajectory maps of Bapong (location indicated with stars) for the DJF (a) and JJA (b) periods during both sampling campaigns. The colour code indicates the percentage of the trajectories passing over 0.2° x 0.2° grid cells superimposed on the southern African map, with the colours red and blue indicating the highest and lowest percentage overpasses, respectively.
form relatively quickly from NO. During daytime the average ratio of $[\text{NO}] / [\text{NO}_2]$ ≈ 0.1 (Seinfeld and Pandis 2016). During night time NO reacts rapidly with $\text{O}_3$ to form $\text{NO}_2$ (Seinfeld and Pandis 2016). Hence, $\text{NO}_2$ acts similar to a primary pollutant, such as $\text{SO}_2$. In contrast, $\text{O}_3$ is a secondary pollutant, formed from the photochemical reaction of $\text{NO}_2$ and with precursor species such as VOCs and CO being important (see discussions in Section 3.2). Therefore, air mass history in relation to $\text{NO}_2$ (as well as VOCs and CO) emissions are vital in understanding $\text{O}_3$. In order to better understand transport of $\text{SO}_2$ and $\text{NO}_2$, as well as regional $\text{O}_3$ formation, 96-hr overlay back trajectory maps were compiled for each of the 10 measurement sites for both sampling campaigns combined. Examples of such overlay back trajectory maps for Bapong and Morokweng are presented in Figure 7. These sites were located on the eastern and western borders of the investigated area in the North West province, respectively. Also, Bapong had the highest and Morokweng the 2nd lowest $\text{SO}_2$ and $\text{NO}_2$ median/mean concentrations during both measurement periods.

As previously indicated, there were numerous large point sources close to Bapong. In addition, it is evident from Figure 7a that Bapong is also frequently impacted by air masses that had passed over other polluted areas, such as the JHB-Pta megacity, the Mpumalanga Highveld and the Vaal Triangle. In contrast to Bapong, the air mass history of Morokweng (Figure 7b) is dominated by anti-cyclonic circulation, but this circulation mostly takes place north of the South African-Botswana border, where much fewer large point sources occur. In addition, air masses from the southwest of Morokweng, where the relatively clear regional background (i.e. Karoo and Kalahari) is situated, affect it fractional more than Bapong.

As indicated earlier, air mass history is also very important to understand $\text{O}_3$. However, since it is a secondary pollutant, and additional phenomena such as titration can occur (Balašhov et al. 2014) a more detailed discussion on it (regional $\text{O}_3$ perspective) is presented later.

As stated earlier, an intensive campaign was conducted during JJA 2019. The JJA period was specifically selected, since $\text{SO}_2$ and $\text{NO}_2$ concentrations typically peaked then (Figures 3a and b, Figures 4a and b). In order to visualise the combined results of the 10 original sites, as well as the 15 additional sites, spatially interpolated average concentrations maps for $\text{SO}_2$, $\text{NO}_2$ and $\text{O}_3$ during JJA 2019 are presented in Figure 8. Historic JJA data for Welgegund, Marikana and Botsalano were also included in these figures. These spatially interpolated average concentrations maps are not perfect, since i) only a limited number of sites could be included in this study and ii) the sites could not be equally spaced over the study area. However, notwithstanding these limitations, valuable information can be gained from the maps.

The $\text{SO}_2$ spatial map (Figure 8a) indicate higher $\text{SO}_2$ concentrations on the eastern side of the study area in the North West Province, than in the west. As indicted earlier, various large point sources occur in the east, that could potentially emit $\text{SO}_2$, whereas in comparison the western region of the study area has no significant industries, thus having lower $\text{SO}_2$ concentrations. Open biomass burning also occur more frequently in the east, if compared to the west of the study area (Figure A3, Appendix). Although open biomass burning is expected to contribute fractionally less than industrial emissions of $\text{SO}_2$ in the context of the study area, savannah and grassland biomes are known to emit 0.47 ± 0.44 g $\text{SO}_2$/kg dry material burnt (Andreae 2019). Recently, Vakkari et al. (2020) reported even higher $\text{SO}_2$ emissions of 1.1 g $\text{SO}_2$/kg for open biomass burning plumes measured specifically at Welgegund in the North-West Province. Hence open biomass burning will also contribute to the higher $\text{SO}_2$ concentrations in the eastern than in the west of the study area.
In contrast to the spatial map for SO$_2$, the NO$_2$ spatial concentrations map (Figure 8b) indicated two areas of higher concentration, i.e. the extreme east near Bapong and the area around Taung. As previously stated, the high number of large point sources and higher population density near Bapong will result in higher NO$_2$ concentrations. Similarly, the higher population density around Taung (Figure A4, Appendix) and associated higher vehicle emissions result in higher NO$_2$ concentrations there. The fact that the additional measurement sites, monitored during the intensive campaign, were situated next to the relatively busy R378 road, likely also contributed to the higher NO$_2$ measured. The lowest NO$_2$ concentrations were recorded at the Ottoshoop and Welgegund sites.

The O$_3$ concentration spatial map (Figure 8c) exhibited almost the inverse spatial trend than the NO$_2$ map (Figure 8b). Particularly the lower O$_3$ measured around the Taung area is of interest. This low O$_3$ concentration area, associated with higher NO$_2$, suggests that O$_3$ is being titrated there during night-time. The spatial map also shows that although significant industrial NO$_2$ emissions do not occur in the western part of the North West Province, non-point source emissions (e.g. vehicle, household combustion and open biomass burning) emit enough NO$_2$ to result in exceedances of the O$_3$ standard limit there.

Conclusions and recommendations

With regard to SO$_2$, the results indicated that it is unlikely that ambient air quality issues are persistent or wide spread in the western, more rural North West Province. Therefore, no monitoring of SO$_2$ is currently required there. It was evident that SO$_2$ was generally higher in the eastern North West Province that is located in, or in proximity to larger point sources. This includes the wBC (Rustenburg/Brits/Sun City area), where one monitoring site (Bapong) was situated. It is therefore recommended that compliance monitoring by industry and/or government in such areas be continued and/or expanded if required.

The atmospheric chemistry of NO$_2$ and O$_3$ are linked to one another, therefore it makes sense discussing them together. The results indicated that widespread exceedances of the 8-hrs. moving standard limit of 61 ppb for O$_3$ is likely across the entire province, even in the more rural western part. Therefore, systematic and continued measurement of O$_3$ would be advisable, in order to quantify the problem and to estimate impacts better. No exceedances of the annual average limit were reported for NO$_2$, nor were any exceedances of the 1-hr. standard limit predicted. However, tropospheric O$_3$ can only form from NO$_2$, hence it would be important to measure NO$_2$ with O$_3$. Measurements of NO$_2$ and O$_3$ in the Taung area would be particularly meaningful, since the spatial maps indicated that O$_3$ is titrated there. The higher NO$_2$ emitted from there is likely a regional source of O$_3$, in addition to regional transport of NO$_2$ from more well-known source areas such as the Mpumalanga Highveld, Vaal Triangle, JHB-Pta megacity and the wBC. Vehicle emissions is also an important source of NO$_2$ across the province, which can only be addressed if the vehicular fleet is updated to higher specification over time and if road worthiness emission regulations are implemented. The release of nitrogen from the fuel consumed during household combustion is also an important source of NO$_2$. 

Figure 8: Spatially interpolated average SO$_2$ (a), NO$_2$ (b) and O$_3$ (c) concentration maps across the area of interest. Spatial interpolations were achieved by using the “grid data” function in Matlab, with triangulation-based linear interpolation.
In future studies, particulate matter with an aerodynamic diameter ≤ 2.5 µm (PM\textsubscript{2.5}) concentrations should be mapped across the province, since the health effect of ambient PM is likely to be more severe than the gaseous species considered in this study. For such a project, passive measurement of PM could also be considered and/or gravimetric filter-based measurements that do not require costly instrument, to make the project feasible. Lastly, it is recommended that possible future studies be augmented by dispersion modelling to at least partially address the non-gradual interpolation of spatial concentrations with triangulation-based linear interpolation that was used here.

Permission to publish
All co-authors agreed to the submission of this paper. The manuscript has not been published or offered elsewhere. Acknowledgment and references have made where required.

Acknowledgments
This work was funded by the Directorate Environmental Quality Management; Rural, Environment and Agricultural Development (READ), of the North West Provincial Government. The Welgegund, Marikana and Botsalano stations were operated through joint South African-Finnish collaboration. This publication also forms part of the output of the Biogeochemistry Research Infrastructure Platform (BIOGRIP) of the Department of Science and Innovation of South Africa, which supports the Welgegund station.

Author contribution
MN conducted the work as part of her MSc study; JPB, PGvZ, VL, PK and SM conceptualised the project; J-SS and MN prepared and analysed all samplers; VL, PK, SM and MN handled sampler logistics; JPB, MN and PGvZ drafted the paper; MK, VV, LL, JPB and PGvZ conceptualised and contributed to the operations of the Botsalano, Marikana and Welgegund stations. All co-authors edited and commented on drafts.
